# Setup Colab

Here we setup Colab, and import some useful packages.

```
from google.colab import drive
drive.mount('/content/gdrive')

Trive already mounted at /content/gdrive; to attempt to forcibly remover the content/gdrive and the content/gdrive; to attempt to forcibly removes.chdir('/content/gdrive/MyDrive/Assignment1/Startpkg_A1')

import random import numpy as no import numpy as no import matplotlib.pyplot as plt from data_process import get_CIFAR10_data import math from scipy.spatial import distance from models import Perceptron, Softmax from kaggle submission import output submission csv
```

## Loading CIFAR-10

%matplotlib inline

In the following cells we determine the number of images for each split and load the images.

```
# You can change these numbers for experimentation
# For submission we will use the default values
TRAIN_IMAGES = 49000
VAL_IMAGES = 1000
TEST_IMAGES = 5000 # Keep this default as 5000 for your submission

data = get_CIFAR10_data(TRAIN_IMAGES, VAL_IMAGES, TEST_IMAGES)
X_train, y_train = data['X_train'], data['y_train']
X_val, y_val = data['X_val'], data['y_val']
X_test, y_test = data['X_test'], data['y_test']
```

Convert the sets of images from dimensions of  $(N, 3, 32, 32) \rightarrow (N, 3072)$  where N is the number of images so that each 3x32x32 image is represented by a single vector.

```
X_train = np.reshape(X_train, (X_train.shape[0], -1))
X_val = np.reshape(X_val, (X_val.shape[0], -1))
X_test = np.reshape(X_test, (X_test.shape[0], -1))
```

This function computes how well your model performs using accuracy as a metric.

```
def get_acc(pred, y_test):
    return np.sum(y_test==pred)/len(y_test)*100
```

## Perceptron

Perceptron has 2 hyperparameters that you can experiment with:

- Learning rate controls how much we change the current weights of the
  classifier during each update. We set it at a default value of 0.5, but you should
  experiment with different values. We recommend changing the learning rate by
  factors of 10 and observing how the performance of the classifier changes. You
  should also try adding a decay which slowly reduces the learning rate over each
  epoch.
- Number of Epochs An epoch is a complete iterative pass over all of the data in
  the dataset. During an epoch we predict a label using the classifier and then
  update the weights of the classifier according the perceptron update rule for
  each sample in the training set. You should try different values for the number of
  training epochs and report your results.

You will implement the Perceptron classifier in the **models/Perceptron.py**. You may directly edit it by open it from the Files icon located on the left sidebar.

The following code:

- Creates an instance of the Perceptron classifier class
- The train function of the Perceptron class is trained on the training data
- We use the predict function to find the training accuracy as well as the testing accuracy

#### → Train Perceptron

```
alpha_list = [0.01]
epochs_list = [200]
decay = 0.8
i = 0

#variables to capture Optimal Hyper-parameters

→ The testing accuracy is given by : 31.000000
```

### Perceptron Kaggle Submission

Once you are satisfied with your solution and test accuracy output a file to submit your test set predictions to the Kaggle for Assignment 1 Perceptron. Use the following code to do so:

```
output_submission_csv('perceptron_submission.csv', percept_.predict(X_te:
```

# Softmax Classifier (with SGD)

Next, you will train a Softmax classifier. This classifier consists of a linear function of the input data followed by a softmax function which outputs a vector of dimension C (number of classes) for each data point. Each entry of the softmax output vector corresponds to a confidence in one of the C classes, and like a probability distribution, the entries of the output vector sum to 1. We use a cross-entropy loss on this sotmax output to train the model.

Check the following link as an additional resource on softmax classification: <a href="http://cs231n.github.io/linear-classify/#softmax">http://cs231n.github.io/linear-classify/#softmax</a>

Once again we will train the classifier with SGD. This means you need to compute the gradients of the softmax cross-entropy loss function according to the weights and update the weights using this gradient. Check the following link to help with implementing the gradient updates: <a href="https://deepnotes.io/softmax-crossentropy">https://deepnotes.io/softmax-crossentropy</a>

The softmax classifier has 3 hyperparameters that you can experiment with:

- **Learning rate** As above, this controls how much the model weights are updated with respect to their gradient.
- Number of Epochs As described for perceptron.
- Regularization constant Hyperparameter to determine the strength of regularization. In this case, we minimize the L2 norm of the model weights as regularization, so the regularization constant is a coefficient on the L2 norm in the combined cross-entropy and regularization objective.

You will implement a softmax classifier using SGD in the models/Softmax.py

The following code:

- · Creates an instance of the Softmax classifier class
- The train function of the Softmax class is trained on the training data
- We use the predict function to find the training accuracy as well as the testing accuracy

#### → Train Softmax

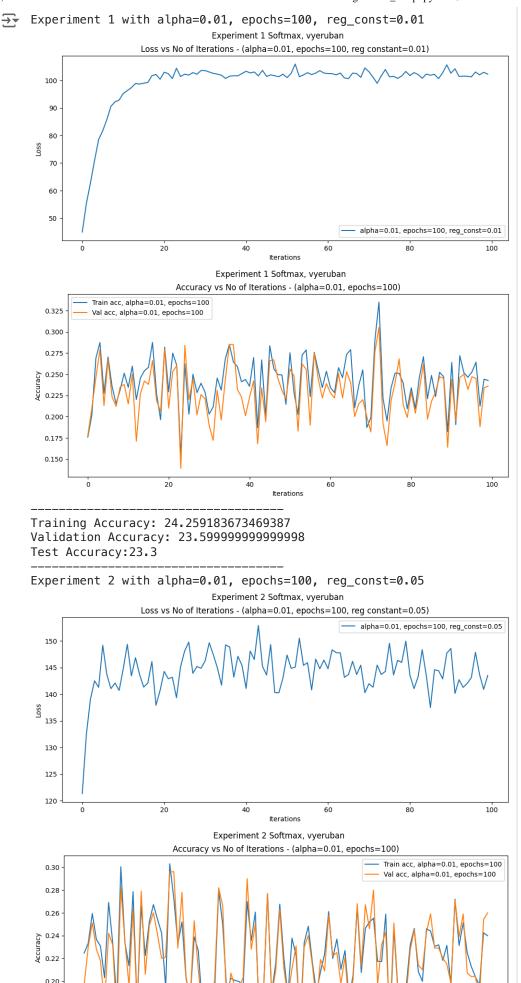

```
